

Functional Programming

Types

Christoph Denzler / Daniel Kröni
University of Applied Sciences Northwestern Switzerland
Institute for Mobile and Distributed Systems

Learning Targets

You

- know what types are
- understand the importance of types in a programming language
- know the basic types in Haskell
- can tell the type of a function

Content

- **Basic concepts**
- **Motivation for types**
 - Why types at all?
- **Basic types**
 - Bool, Char, String, Int, Integer, Double
- **Own types**
 - `data Color = Red | Yellow | Green`
- **Tuple types**
 - `(True, "Hallo", 5) :: (Bool, String, Int)`
- **Function types**
 - `add :: (Int, Int) -> Int`
- **Type classes**

What is a Type?

- Values are represented by data – usually bits (0 | 1).
- Without proper interpretation, data is of no use. It is only a vast accumulation of bits.
- Abstraction from low level representation
- **Types add meaning to plain bits**
- Type systems prevent us from accidentally mixing up types
E.g. `not :: Bool -> Bool`
 - `(not True)` is ok
 - `(not 2)` does not make sense: The function `not` is not applicable to Integers

A type is a set of related values

Why Types?

Last week:

- The function “+” can add two numbers and will provide the sum (a number again) as its result

What will happen if we try to

Worksheet: Types

Key learnings:

"if a piece has the wrong shape, it simply won't fit"

Haskell

Python* and JavaScript

What is a Type?

Many programming languages distinguish between

- **Basic Types** (*Types that cannot be made up of other types*)
 - *Bool*
 - *Char*
 - *Int*
 - *Integer*
 - *Double*
- **Enumerations**
- **Aggregated Types**
 - Tuples
 - GPS Coordinates: an aggregation of (Longitude, Latitude)
 - Address: an aggregation of (name, street, postal code, city)
 - Lists
 - Path / Directions: the way from Brugg to Zurich as a list of GPS Coordinates / waypoints
- **Function Types (see later)**

Type declaration

Expression :: Name_of_Type

Examples:

```
True :: Bool  
not False :: Bool  
'\n' :: Char  
"c" :: String
```

**Type names must
start with capital
letters!**

Use the command `:type` or `:t` to find out the type of an expression

```
> :type True  
True :: Bool  
> :t not False  
not False :: Bool  
> :t 'c'  
'c' :: Char
```

Basic Types

- **Bool**

- The two logical values `True` and `False`
- The common infix operators and functions are provided
 - `a && b` (AND)
 - `a || b` (OR)
 - `not a` (NOT)

- **Char**

- This type contains all single characters that are available from a normal keyboard such as 'a', 'A', '3', and '?'
- Some characters have special meaning such as '\n' (newline) and '\t' (tab)
- All characters are enclosed in single forward quotes `' '`

Basic Types

- **Int**
 - Fixed precision integers such as 100, -3, 0 etc.
 - Possible integers: from -2^{63} to $2^{63}-1$
 - Uses a fixed amount of memory (usually 64 bits), CPU supported, fast
- **Integer**
 - Contains **all** integers, with as much memory as necessary being used for their storage.
 - Slower computations as type is not supported by CPUs
- **Double**
 - Floating point numbers
 - Contains numbers with a decimal point such as 3.14159, -12.8
 - Uses a fixed amount of memory (usually 64 bits), CPU supported, fast

Defining your own Enumeration Types

```
data Color = Red | Yellow | Green
  deriving (Show)
data ToDo = Stop | Wait | Go
  deriving (Show)
```

- **Defines two types: Color and Todo**
 - Color has three possible values: Red, Yellow, Green
 - ToDo has three possible values: Stop, Wait, Go
- **For example, Red is a value of type Color:**
Red :: Color

Aggregated Types - Tuples

- A tuple is a **finite sequence** of components of **possibly different** type
- **Syntax:** component types are enclosed in round brackets and separated by commas

```
(False, 8, "Hallo")  
(8, 'a', True, "Text")
```

- The type of a tuple is written as (T_1, T_2, \dots, T_n) and thus defining the type at each position in the tuple
- The **number of components** in a tuple is called its **arity**

```
> :t ('a', True, 'b')  
('a', True, 'b') :: (Char, Bool, Char)  
> :t ( (True, '8'), ('e', False, 'x') )  
( (True, '8'), ('e', False, 'x') )  
  :: ((Bool, Char), (Char, Bool, Char))
```

Accessing components in a pair

- Pairs are tuples with only two components (of arity 2). Eg.

```
(5, 2)  
(False, 'c')
```

- There are two selector functions in Haskell to get the first and the second component of pairs:

```
fst :: (a,b) -> a  
fst (x, y) = x
```

```
snd :: (a,b) -> b  
snd (x, y) = y
```

Polymorphic Types

- The first component of a tuple can be accessed as follows:

```
> fst ("Yes", 1)
"Yes"
> fst (("Hallo", 'c'), 1)
("Hallo", 'c')
```

- But what is the type of `fst`? We used it with different types of tuples?

```
> :t fst
fst :: (a, b) -> a
```

- Aha, but what are 'a' and 'b'?

Polymorphic Types

```
> :t fst  
fst :: (a, b) -> a
```

Does not start with
capital letter, therefore
no type!

- **a** is a **type variable**, it represents any type
- A type that contains at least one type variable is called **polymorphic type** ("of many forms").
- Thus `fst` is a **polymorphic function**.
- Using polymorphic types, functions can operate on many different types.
 - Less code
 - Less error prone
 - Behavior always the same, regardless of types used

Type Synonyms

- The keyword **type** can be used to introduce a new name (a synonym) for an existing type. E.g.

```
type Coord = (Int, Int)
```

- This does not create a new type, only a new name!

- The synonym and the original type can be used interchangeably

```
xCoord :: Coord -> Int  
xCoord (x, y) = x
```

```
time :: (Int, Int)  
time = (23, 59)
```

```
xCoord time -- compiles
```

- Good for documentation but no help from the compiler

Worksheet: Tuples

Key learnings:

Function Types

- Functions also have a type. It consists of
 - The type of the input parameter
 - The type of the output parameter
- Functions with one input type and one output type are defined as:

```
functionname :: Inputtype -> Outputtype
```

- Examples

```
not           :: Bool -> Bool  
isDigit      :: Char -> Bool  
isUpperCase  :: Char -> Bool
```

- Note that isDigit and isUpperCase have the same type!

Declaring our own function

- A **declaration** of a function:

```
atTrafficLight :: Color -> ToDo
atTrafficLight Red      = Stop
atTrafficLight Yellow = Wait
atTrafficLight Green   = Go
```

- declaration by **pattern matching**
 - one equation for each possible value of the input parameter
- an **application** of a function:

```
> atTrafficLight Yellow
Wait :: ToDo
```

Functions with multiple parameters

We write:

		Parameter types		Result type
<code>add</code>	<code>::</code>	<code>Int -></code>	<code>Int -></code>	<code>Int</code>
<code>add x y</code>	<code>=</code>	<code>x + y</code>		
<code>less</code>	<code>::</code>	<code>Int -></code>	<code>Int -></code>	<code>Bool</code>
<code>less x y</code>	<code>=</code>	<code>x < y</code>		

The last type is the result type, all preceding types are parameter types.

For now read as: "less is a function that returns a Bool as result type and takes two Ints as parameters".

These are **curried** functions.
What this is will be explained later!

Type Inference

```
abbreviate Red      = 'r'  
abbreviate Yellow = 'y'  
abbreviate Green   = 'g'
```

- The type of a function needs not to be specified
- In most cases it can be automatically inferred
- This automatism is called **type inference**

```
> :t abbreviate  
abbreviate :: Color -> Char
```

**Types are the single most
important unit of documentation!**

Typeclasses

- **Polymorphic types are very handy but not all functions can be defined as generic as fst!**
The type of the first component in a tuple is completely irrelevant in the context of fst.
- **Let's have a look at the function abs that computes the absolute value of a Number.**

```
> :t abs  
abs :: Num a => a -> a
```

abs only makes sense for Numeric types like Int or Double, it does not make sense for Char or Bool or any other type.

This can be marked by a **class constraint**. In this case we constrain a to be of the class Num (which is a predefined class that represents numeric types)

Basic classes

- **Eq** – equality types
 - Contains types whose values can be compared for equality and inequality
 - methods: (`==`), (`/=`)
- **Ord** – ordered types
 - Contains types whose values are totally ordered
 - methods: (`<`), (`<=`), (`>`), (`>=`), `min`, `max`
- **Show** – showable types
 - Contains types whose values can be converted into strings of characters
 - method `show :: a -> String`
- **Num** – numeric types
 - Contains types whose values are numeric
 - methods: (`+`), (`-`), (`*`), `negate`, `abs`, `signum`

Basic classes

- **Integral** – integral types
 - Contains types that are numeric but of integral value
 - methods: div, mod
- **Fractional** – fractional types
 - Contains types that are numeric but of fractional value
 - methods: (/), recip

How to write your own classes: see later!

Computing with Numbers

- Haskell does not automatically convert numeric types!
- Numeric literals like 23 or 1.5 are polymorphic in Haskell

```
23 :: Num a => a
```

```
1.5 :: Fractional a => a
```

```
> 3 / 1.5
```

```
2 :: Fractional a => a ✓
```

```
> (3 :: Int) / 1.5 ✗
```

- Use fromIntegral to convert from Int / Integer back to Num a

```
fromIntegral :: (Integral a, Num b) => a -> b
```

```
> fromIntegral (3 :: Int) / 1.5
```

```
2 :: Fractional a => a ✓
```
